Erklärung zur Abschlussarbeit gemäß §22 Abs. 7 APB TU Darmstadt

Hiermit versichere ich, Tim Lange, die vorliegende Bachelorarbeit gemäß §22 Abs. 7 APB der TU Darmstadt ohne Hilfe Dritter und nur mit den angegebenen Quellen und Hilfsmitteln angefertigt zu haben. Alle Stellen, die Quellen entnommen wurden, sind als solche kenntlich gemacht worden. Diese Arbeit hat in gleicher oder ähnlicher Form noch keiner Prüfungsbehörde vorgelegen.

Mir ist bekannt, dass im Falle eines Plagiats (§38 Abs. 2 APB) ein Täuschungsversuch vorliegt, der dazu führt, dass die Arbeit mit 5,0 bewertet und damit ein Prüfungsversuch verbraucht wird. Abschlussarbeiten dürfen nur einmal wiederholt werden.

Bei einer Thesis des Fachbereichs Architektur entspricht die eingereichte elektronische Fassung dem vorgestellten Modell und den vorgelegten Plänen.

Darmstadt, 19th May 2021		
	T. Lange	

1. Introduction

Smartphones are a companion in our daily lives. We use them to keep track of our appointments, manage contacts, navigation and much more. Smartphones need to process and store sensitive data to provide these convenient functionalities. In most mobile ecosystems, the users are not limited to the default-shipped apps but also can install apps from third parties. Android is the market-leading operating system and mobile ecosystem for smartphones, with a market share of over 71% [27]. The most common way to distribute third-party apps is through app stores [20]. Google Play, Android's default app store, allows developers to publish their apps for a small fee. The Play Store currently offers nearly three million apps of all kinds from hundred of thousands of developers [15]. The issue, however, is that every third-party app is a threat to the privacy of the user. The mobile ecosystem is known for tracking where apps send identifying information to an advertiser for individually tailored ads to the user or even sell the user's data [8, 12]. Third-party apps developed by unaware or careless developers might include vulnerabilities that allow compromising the user's data [7]. Moreover, some malicious players try to sneak potentially unwanted programs into the app stores trusted by millions [30].

As a counteract, Android offers a permission system to specify which data or resources an app can access. There are multiple categories for permission. Normal permissions are granted at installation automatically but are displayed in a submenu on the store page. Dangerous permissions need confirmation from the user at runtime. Android guarantees that an app only accesses resources and data for which it has permission to do so. While the permission system helps identify blatant misuses of resources and data, e.g., a flashlight app that wants to access the location, it is far from eliminating the problem. For example, the internet permission is a normal permission meaning an app can access the whole internet without any explicit confirmation. A user has no option to make finer-grained settings.

¹Source: https://developer.android.com/guide/topics/permissions/overview (visited on 20.04.2021)

Researchers all around the world have identified the issue of the insufficient auditing of published apps. One possible solution academia came up with is data flow analysis which tries to identify data flows through a program. Several tools for the Android ecosystem have been proposed [14, 47, 45, 26], one of which is FLOWDROID [6].

FLOWDROID is a precise static data flow analysis tool to detect privacy leaks in Android apps and is the de-facto standard for data flow analysis on Android apps [6]. Like other data flow analyses [23, 29, 2], it is based on the IFDS framework, a theoretical framework for interprocedural data flow analyses that computes the solution by transforming it into a graph reachability problem [32]. Because the algorithm works on a graph, we can now link between data flow analyses and graph search. In graph search, the direction of the search influences the visited nodes and consequential also the runtime.

To this day, all data flow analyses based on IFDS either have one fixed search direction [6, 2, 29] or are adjusted for a narrow use case [23]. Thus, in this thesis, we extend FlowDroid with an alternative implementation to provide a backward-directed data flow analysis leveraging FlowDroid's Android lifecycle modeling and library summaries. The choice between both directions comes in handy when applying the data flow analysis to various applications. Lerch et al.[23] already identified that a backward data flow analysis is beneficial if there is a single goal but a magnificent amount of possible starting points. A prime example is a search for a hardcoded key provided to a cryptographic implementation. Currently, solving this task using FlowDroid is only possible by making a brute-force approach by marking all constants as a starting point. With a backward analysis, it is as easy as using the variable containing the key as the starting point, which should yield much better performance. Besides such natural cases, another analysis direction can also significantly reduce the runtime depending on the given graph.

Our backward analysis should be as sound and precise as the existing forward analysis. Furthermore, we aim at least for a similar runtime performance on real-world apps. On top, to fully utilize the potential of the direction choice, we investigate possible heuristics to predict the favorable direction. We define our research questions as follows:

RQ1: How efficient is the backward analysis in terms of runtime and memory consumption compared to the forward analysis?

RQ2: Is there an apriori known parameter to decide which analysis is more efficient for a given app?

Outline First, we explain the background and the concepts used in static data flow analysis in chapter 2. In chapter 3, we define the flow functions for the IFDS analysis and briefly discuss the impact of the direction on the runtime. We document the extensions we made to FlowDroid in chapter 4. In chapter 5, we validate that our implementation is as sound and precise as FlowDroid's existing implementation. Then in chapter 6, we evaluate our implementation on 200 apps from the Google Play Store. Based on the evaluation, we answer the research questions. We give an overview of the related work, primarily focusing on other backward-directed taint analyses, in chapter 7 before coming to the conclusion of this thesis in chapter 8.

2. Background

In this chapter, we introduce the necessary background. In section 2.1, we explain the term static data flow analysis. We introduce concepts used to solve data flow problems precisely in section 2.2 and section 2.3. We reason the need for a more manageable code representation in section 2.4. Finally, we introduce FlowDroid, the tool our work is based on, in section 2.5.

2.1. Static Data Flow Analysis

In the field of compilers, there is a distinction between static and dynamic. Static generally refers to something that is decided at compile-time, while dynamic refers to runtime decisions [1]. The same distinction is also present for analyses. Dynamic analysis observes the program's runtime behavior, while static analysis works on a representation of the code. Both have different tradeoffs. Achieving good code coverage is a challenge in dynamic analysis. In contrast, a static analysis often can not infer runtime properties, hence follows paths never taken at runtime, also called *infeasible paths* [3]. Thus the dynamic analysis is an underapproximation and static analysis is an overapproximation. In the following, we only consider static analysis.

Data flow analysis is a broad term for analyses that try to identify data flows through a program. Khedker [18] defines data flow analysis as follows:

Data flow analysis is a process of deriving information about the run time behavior of a program.

Data flow analyses are used in many different ways. Compilers use it to apply optimizations, others use it for software verification and it is also used for reverse-engineering [18]. A special kind of data flow analysis is taint analysis, which concepts might be familiar from code reviews. In taint analysis, the goal is to determine whether a particular variables'

information contents flow through the program to another variable. Variables that contain valuable information are *tainted*. This valuable information has to come from somewhere, the so-called *sources*. Sources can be any expression but are often methods. Values produced from sources are considered tainted. On the other end, *sinks* leak valuable information. A data flow between a source and a sink is called a *leak* [3]. For example, to detect apps tracking the user using taint analysis, sources could be methods returning a unique identifier and sinks could be methods that sent out data to the internet. When finding a leak, we know the receiving server can identify the device.

There is also a categorization for data flow analyses. Sensitivities describe whether an analysis is capable of considering an aspect. There are five common sensitivities [18, 3]:

- Flow Sensitivity: A flow-sensitive analysis can determine if a fact holds at a particular statement.
- **Context Sensitivity**: An interprocedural analysis can distinguish the context of a called method, e.g., knows the original call site at a return statement.
- Object Sensitivity: An analysis can distinguish field accesses on different objects.
- **Field Sensitivity**: An analysis can distinguish different field accesses on the same object.
- Path Sensitivity: An analysis takes conditional branches into account, e.g., the condition holds after the branch.

We also need a representation for the information the analysis gathered: the data flow fact. A *data flow fact* is a logical assertion that is either true or false at a statement. Now, there are two different kinds of facts: may and must. For a must analysis, the fact must hold on all paths to this statement, while a may analysis only guarantees the fact holds on one path. The decision of which kind fits depends on the type of data flow analysis. Taint analyses like FlowDroid are based on the may analysis [3].

The analysis direction of a data flow analysis is also decided by the problem to be solved. A live variables analysis computes whether a variable is read before written in the future to eliminate potential dead assignments. A backward pass traditionally solves the problem. On the other hand, a reaching definitions analysis finds out if a definition reaches a statement without an intermediate assignment, usually solved by a forward pass. Additionally, there are also data flow analyses for which the direction is a design choice. For example, program slicing identifies a slice, a subset of the program's statements, which influence a statement (backward pass) or are influenced by a statement (forward pass). Taint analysis, on the other hand, can be solved in both directions with the same results [18].

2.2. IFDS

2.2.1. Original Definition

Interprocedural finite distributive subset (IFDS) problems are a special class of a data flow analysis problem. Generally, the solution to a data flow problem is the meet-over-all-paths (MOP) solution, which is undecidable [33]. However, all problems adhering to IFDS can be transformed into a graph-reachability problem and consequently, the solution is computable in polynomial time. It is context-sensitive and flow-sensitive by default [32].

IFDS operates on a so-called exploded supergraph. Every node in the exploded supergraph is a tuple $\langle s,d\rangle$ of a statement s in the interprocedural control-flow graph and a data flow fact d. The domain is typically the set of variables in the program. Edges between two nodes $\langle s,d\rangle$ and $\langle s',d'\rangle$ exist if d propagated over s yields d' and s' is a successor of s. Propagating facts along the control-flow graph already ensures flow-sensitivity.

```
matched \rightarrow (i matched)_i matched \mid \epsilon
valid \rightarrow valid (i matched)
```

Figure 2.1.: Context-Free Grammar proposed by Reps et al.[32]

To achieve context-sensitivity, Reps et al. proposed a context-free grammar (c.f. Figure 2.1). Each call site gets a unique index, outgoing call edges are labeled with (i) and incoming return edges is taken and (i) and incoming valid models a partially balanced path, e.g., after a call for which the return is still pending. A path between two nodes is called (i) and (i) are incoming in (i) and (i) and (i) are incoming (i) and (i) and (i) are incoming (i) and (i) and (i) are incoming (i) and (i)

To propagate facts over statements, we need to define rules on how the data flow changes when observing a statement. These rules are called flow functions. There are four types of flow functions: [32]

```
void foo(){
   int i = 0;
   int j = bar(i);
   int k = bar(j);
   return p + 42;
   return k;
}
```

Figure 2.2.: Context-Sensitivity using a Context-Free Language

- **Call Flow**: Edges from call statement into a method. The flow function maps the facts visible in the callee into it.
- **Return Flow**: Edges returning from a method. The flow function maps the facts visible in the caller out of the callee.
- **Call To Return Flow**: Edges over a call statement. The flow function maps the facts not visible in the callee over the call statement.
- **Normal Flow**: The default case. Handles edges over every other statement, for example, assignments.

The incoming set of facts is all predecessors' outgoing facts merged using a merge operator □:

$$in(s) := \prod_{p \in Preds(s)} out(p)$$

Now, we also want to introduce new facts. For that reason, the domain contains a zero fact and all nodes with $d=\mathbf{0}$ are always reachable; thus, the zero fact is a tautology. Whenever we want to introduce a fact, we can model this in the flow function by deriving such facts from the zero fact [32]. For example, in taint analysis, the flow functions map zero facts at sources to a tainted variable.

IFDS also utilizes summaries. After returning from a method, the algorithm solved a subproblem for which it remembers the results to be applied later. So, the proposed tabulation algorithm for solving the realizable path problem is a dynamic algorithm [32].

Eventually, the worklist is empty as there are no facts to propagate anymore and the analysis will terminate. There are two ways for a fact to be not propagated further. Either a flow function killed the fact or the same fact was already observed at a statement, meaning the IFDS analysis reached a fixpoint [32].

However, we already started this section, hinting not all problems can be formulated in the IFDS framework. The restrictions the problems have to abide by are eponymous in IFDS and explained in the following paragraphs.

Distributive The flow function must be distributive over the merge operator. Formally, $f(x \sqcap y) = f(x) \sqcap f(y)$ must hold at any time. Informally speaking, it does not matter whether facts get merged before or after applying the flow functions. Distributiveness is essential for the correctness of IFDS because only if the flow functions are distributive, the maximum fixed point (MFP) equals MOP and MFP is computable in polynomial time [18, 32].

Finite Another restriction is that the set of data flow facts has to be finite. Let us go by a counterexample of what IFDS is not capable of: Answering "Which value is stored in variable x at statement s?". Now the data flow fact is a tuple of the variable together with the stored value $\langle x,v\rangle$. Consider Figure 2.3. x is initialized to an empty string and in every loop iteration, "a" gets appended to the string. The value of x changes every time and never repeats itself. In theory, the algorithm will never observe a taint twice in line 4. Because the algorithm can not reach a fixpoint, it will not terminate. In practice, every data type is bounded either by the heap or stack size, but the domain is cubic in the time-complexity $O(|E| \cdot |D|^3)$ making IFDS infeasible for large domains [32].

Figure 2.3.: Finiteness example

Subset Data flow frameworks need to deal with merging the outcoming sets to a single incoming set. Essentially, to formalize the approximation and satisfy ordering constraints, data flow frameworks rely on lattices [18]. IFDS also defines an underlying lattice on the powerset of the domain. The lattice ordering must be set inclusion. Therefore, the merge operator is set union or set intersect. Now recall may and must from the last subsection. Here we can see the connection between the merge operator and may or must. The paper by Reps et al. later decides on set union due to the duality of must and may not [32]. This decision is also efficient in practice, as discussed in the following subsection.

2.2.2. Practical Extensions

The original definition is inefficient in practice. Among others, Naeem et al. proposed practical extensions to the IFDS framework to perform better in practice [28].

The original algorithm demands a fully built exploded supergraph. Even in moderate programs, the domain can get quite large. As the nodes in the exploded supergraph are the cross-product of the domain and interprocedural call-graph nodes, it is infeasible to generate the full graph beforehand. Because there is no way to know before which part of the supergraph the analysis demands, they propose to generate it ad-hoc. That also removes the restriction on a small domain. Now IFDS is also feasible if the domain's encountered subset is small enough [28]. The restrictions on the domain set can be loosened even more. Bodden suggests the domain can be infinite in practice. Only the observed facts must adhere to the ascending-chain condition over the flow functions when using the on-demand supergraph [9].

Also, the original IFDS definition ignores the type structure of the programming language. Type information can be used to kill facts due to impossible casts. Also, facts with the same variable but different types can be merged with the superclass as its new type [28].

Furthermore, the original definition starts the IFDS algorithm at the entry point of the interprocedural call-graph. As described in subsection 2.2.1, a flow function can derive an initial fact from the zero fact if needed. If the methods where initial facts will be introduced are known a priori, the supergraph can be traversed without applying flow functions until such a method is found on the path. This optimization introduces unbalanced problems where a method returns but no corresponding call site is found, which can be solved by a small extension to the tabulation algorithm. Lerch et al. first described the extension [24] and it is also present in FLOWDROID [3].

Another optimization is possible if the merge operator is set union thanks to the $A\subseteq A\cup B$ property of set union. There is no need to wait for other predecessors to finish as a set is always a subset of a union with itself and another set. Hence, the IFDS solver can skip the in-set construction and immediately propagate the outcoming facts as singleton sets, sometimes referred to as point-wise propagation. Especially parallelized IFDS implementations benefit from point-wise propagation [34].

2.3. Access Paths

We have already seen IFDS fulfills context- and flow-sensitivity by default. Now, a precise analysis for Java also needs object- and field-sensitivity. Thus, we also need to model the heap.

Access paths are one possible heap model. They consist of a list of field dereferences linked to a tainted variable of a reference type [18]. Note, this increases the domain size because now not only "object o is tainted" is a data flow fact, but also all of its fields can be tainted. Especially when encountering recursive data structures with loops such as doubly-linked lists, this gets problematical. Consider Figure 2.4, the loop would let the observed domain grow indefinitely and never reach a fixpoint. As a solution, access paths are limited in length, which is also called k-limiting, whereas the constant k is the maximum access path length. If an access path passes this length, it is cut off and the entire last reference is considered tainted. This cut-off comes with a loss of precision [17]. Consider again Figure 2.4. With k=2 the analysis would reach the fixpoint lst.next.prev.* after two iterations.

Figure 2.4.: Infinite Access Path

Although with k-limiting, the algorithm terminates, it does have another problem. After a loop like in Figure 2.4, the access path is polluted with a dereference chain to its base object even though the next.prev dereference could be omitted without precision loss. As

a solution, Deutsch proposed symbolic access paths, which try to eliminate loops in access paths [11]. In practice, Deutsch's approach needs some adaptions as he only considered fields but not base objects and he defines loops simply by type [3]. With symbolic access paths k-limiting is theoretically obsolete but still often applied to speed up the analysis.

2.4. Intermediate Representations

Most compilers these days use intermediate representations (IRs). IRs are an equivalent representation of the source code but are less complex and more regular and are typically not architecture-dependent. They are often in an interchangeable format and can be saved as text to be used by various tools [38]. Such an IR allows compilers to apply machine-independent optimizations to the code without worrying about complex expressions in the source code or reimplementing the optimization for each architecture.

The Java Virtual Machine (JVM) also operates on an IR called Java bytecode. The JVM is mostly stack-based and so is the Java bytecode. In Figure 2.5 is an example of a simple code snippet translated to Java bytecode. Simple expressions such as c = a + b translate into multiple statements and there is no fixed length of an expression in the bytecode. The analysis would also have to reconstruct the expressions ad-hoc. Furthermore, Java bytecode has over 200 possible instructions¹, which need to be considered and only knows primitive types and references. Concluding, stack-based IRs are suitable for just-in-time interpretation but inconvenient for data flow analysis [42].

```
1 bipush 21 // push 21
2 istore_1 // store in register 1
3 bipush 21 // push 21
4 istore_2 // store in register 2
5 iload_1 // push a
1 int a = 21;
6 iload_2 // push b
2 int b = 21;
7 iadd // pop a & b and push a + b
3 int c = a + b;
8 istore_3 // store in register 3
(a) Java code
(b) Java bytecode
```

Figure 2.5.: Java bytecode example

¹Source: https://docs.oracle.com/javase/specs/jvms/se8/html/ (visited on 17.04.2021)

A more convenient representation for static analysis is three-address codes. Each statement consists of up to three operands and is either an assignment or a control-flow statement. Operands are represented by variables instead of registers or stacks. Such a representation fixes the expression length to be better suited for static analysis than assembly. It also reduces the possible combinations to a manageable amount compared to the source code written by a human [1].

Jimple is a three-address intermediate representation and can be constructed from the Java and Dalvik bytecode, the IR used for Android apps. It is a high-level representation and its syntax is close to Java. Complex statements are split up into multiple statements. For example, there can be only one field reference per statement and arguments are always local variables or constants [42]. This groundwork dramatically reduces the possible cases the data flow analysis needs to consider and eases the analysis.

2.5. FlowDroid

FLOWDROID is a precise context-, flow-, object- and field-sensitive static taint analysis tool for Android apps[6]. Since its initial release in 2014, it is actively maintained and gained traction in research and academia². It is based on Soot, a Java optimization framework, which later has been extended for static analysis [22]. Soot provides the call graph and the conversion from Java and Dalvik bytecode to Jimple, the intermediate representation of choice for FLOWDROID [3].

Androids activity-lifecycle concept does not have a single entry point; instead, multiple callbacks are a possible entry point. Also, an Android app can contain multiple components and register callbacks in various of Android's standard libraries. FLOWDROID models the entire Android lifecycle to be precise and generates a dummy main method to provide a single entry point for the call graph generation. [6].

FLOWDROID inherits flow- and context-sensitivity from IFDS and the object- and field-sensitivity from symbolic access paths. To provide precise results even with aliases in use, FLOWDROID comprises an alais analysis. The alias analysis is encoded as another IFDS problem and resolves all encountered aliases on-demand. The two IFDS analyses are intertwined to maintain flow- and context-sensitivity between both analyses[6].

²Source: https://github.com/secure-software-engineering/FlowDroid (visited on 17.04.2021)

³Source: https://developer.android.com/guide/components/activities/activity-lifecycle (visited on 17.04.2021)

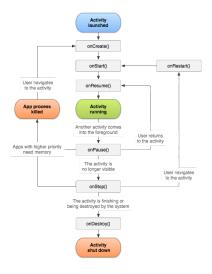

Figure 2.6.: Activity Lifecycle³

The implementation of FlowDroid is modular, easily extensible and offers many additional features. Two of them are noteworthy for this work: native call handler and taint wrappers. As both Java and Android allow calling native methods, FlowDroid also needs to model those cases. It currently does not support the analysis of those methods but contains rules for essential methods. The second feature is taint wrappers. They allow defining rules for methods, e.g., from a commonly used feature such as StringBuilder, which allows the taint analysis to skip the method and apply a summary [6]. StubDroid, an extension to FlowDroid by Arzt et al., allows precomputing summaries using FlowDroid and serializes them in an XML format for tool-independent use. These summaries are handy for real-world applications where third-party libraries are often used [5].

3. Theory

In the first part of this chapter, we define the flow functions for the IFDS analysis. In the second part, we discuss taint analysis's runtime, highlighting possible differences between forward and backward analysis.

3.1. Flow Functions

We describe the flow functions' behavior based on the Jimple language and define semiformal rules analogous to the publication[3] on FlowDroid. These rules only focus on the basic language constructs. We describe flows for additional language features such as arrays and exceptions later and more informal in section 4.3.

3.1.1. Normal Flow

Normal flow functions handle every statement that does not contain an InvokeExpr. For the base cases in normal flow, new taints are only produced at assignments. Assignments are always explicit in Jimple and are either AssignStmts or IdentityStmts. The IdentityStmt's are at the top of a method¹ and assign special values to locals, e.g., parameters and the this reference. We perform the identity function over those because we want to keep those taints alive to reach the return edge. Then the Return Flow function takes care of mapping all parameters back into the caller². So in the following, we only consider AssignStmts.

¹With the exception of local_name := @caughtexception, which is outside of the base cases.

²Note that traversing the interprocedural control-flow graph backward means call edges are now return edges and vice versa.

Now, let us consider an AssignStmt where the left side is either a field reference or a local and the right side is an expression. In the following, we assume the right side is always a local or a field dereference. If the expression is an InvokeExpr, we handle this in the call flow. For unary operators, the local can simply be extracted and for binary operators, we consider both locals separately. An assignment has the structure $x.f^n \leftarrow y.g^m$ with $n,m \in \{0,1\}$ modeling a possible field reference. As taints may have an access path of an arbitrary length, we denote this as $h^k.^3$ Jimple also ensures only one field dereference per statement, which Arzt chose not to represent in the semi-formal definitions and neither did we.

In the first case, we look at exact matches. Either we have an assignment with a local (n=0) or a field dereference (n=1). For both, the base variable needs to match. For the latter, also the first field of the access path has to match the field dereference. The first field dereference is removed from the taint and the remaining access path is copied to the newly created taint. The incoming taint is killed because, thinking forward, it received the taint at this statement.

Rule 1: An incoming taint $T = x.f^n.h^k$ with $k \ge 0$ produces the outflowing taint set $\{y.g^m.h^k\}$.

Next, we need a rule for the case the field dereference f is included in a cut-off approximation. Recall section 2.3, symbolic access paths can also be k-limited to speedup the analysis and are k=5-limited in FlowDroid by default. Thus, we might encounter a taint with no field dereferences and a wildcard * appended. In this case, just the base needs to match. However, this time, the left side is kept alive because we can not reason which field is tainted due to the cut-off approximation.

Rule 2: An incoming taint T = x.* with $k \ge 0$ produces the outflowing taint set $\{y.g^m.*, T\}$.

Lastly, we could also observe a taint on the right side. In this case, we apply the identity, so propagate the taint over the statement. This case is necessary later when we consider aliasing in section 4.2.

Rule 3: An incoming taint $T = y.g^m.h^k$ with $k \ge 0$ produces the outflowing taint set $\{T\}$.

Rule 4: An incoming taint T = y.* produces the outflowing taint set $\{T\}$.

 $^{^3}h^k$ is a k-length chain of field dereferences, not k-times the same field dereference

Whenever a taint neither matches on the left nor the right side, we also perform the identity as the statement does not touch the tainted variable's contents.

3.1.2. Call Flow

The Call Flow function and subsequently Return and Call To Return Flow function apply whenever a statement contains an InvokeExpr. For call statements without an assignment, we have statements of the structure $o.m(a_0,...,a_n)$ with $n \in \mathbb{N}$. a_i denotes the i-th argument, p_i the corresponding parameter to a_i and c the class instance of the callee's base object.

When we encounter a tainted argument in the caller, the taint needs to go through the callee. Java uses pass-by-value, so the arguments are copied into the callee. Thus, for primitives, the value is copied and pushed on the stack. For reference types, the pointer to the object is pushed on the stack. In the second case, if only the base reference is tainted but nothing more (k=0 and no wildcard), the callee can only access and overwrite the reference saved in the parameter on the stack but is not able to change the reference in the callee. We know an update that tainted the primitive or reference without field dereferences can not be inside the callee due to the backward direction. This property becomes apparent when we get specific to Java's types. Primitives do not have fields and strings are immutable⁴. Consider the example in Figure 3.1. On the left, we use the built-in String type. In line 2, str is copied into callee. After this statement, both str hold the value 42 but point to another memory location⁵. Thus, main carries on with the original value of str no matter what callee writes to str. In contrast, on the right, the callee can update the field on the heap. Therefore, the taint needs to be propagated into the callee to find the leak. Conclusively, k needs to be greater than 0.

Rule 1: An incoming taint $T = a_i . h^k$ with $k > 0 \land 0 \le i \le n$ produces the outflowing taint set $\{p_i . h^k\}$.

Rule 2: An incoming taint $T = a_i.*$ with $0 \le i \le n$ produces the outflowing taint set $\{p_i.*\}$.

⁴The special handling of strings results in transparent fields, e.g. we can treat strings as if they were primitives in this case.

⁶The JVM might only set a copy-on-write flag on str in callee and point it to the identical location as str in main to save memory. At least right before the update happens, it is guaranteed that the variable points to a different location.

```
1
                                          void main() {
   void main() {
                                       2
1
                                               Some0bject o = new
2
        String str = "42";
                                                   \hookrightarrow SomeObject();
3
        callee(str);
                                       3
                                               callee(o);
4
        sink(str); // no leak
                                       4
                                               sink(o.str); // leak
5
   }
                                       5
                                          }
6
                                       7
   void callee(String str) {
                                          void callee(SomeObject o) {
8
        str = source();
                                       8
                                               o.str = source();
9 }
                                       9
                                          }
      (a) Taint Without Fields
                                                     (b) Taint With Fields
```

Figure 3.1.: Call Flow Example

A non-static callee can also access instance fields of the base object. When we observe a tainted base object, the taint also needs to flow through the callee. The tainted object transforms into a *this* reference. In Java, this references the current instance the method operates on.

Rule 3: An incoming taint $T = o.h^k$ with $k \ge 0$ produces the outflowing taint set $\{this_c.h^k\}$.

Rule 4: An incoming taint T = o.* produces the outflowing taint set $\{this_c.*\}$.

Static fields form a special case. Their scope extends over the whole program and thus, tainted static fields always have to go through the callee. The taint is untouched as the access to those is the same everywhere.

Rule 5: An incoming taint $T = S.f.h^k$ with $k \ge 0$ produces the outflowing taint set $\{T\}$.

In Jimple, AssignStmts can also consist of an InvokeExpr on the right side. The structure of the statement is in this case $x \leftarrow o.m(a_0,...,a_n)$. r_i denotes a return value. m is the number of return statements in the callee. If we observe such a statement and the left side is tainted, we need to map the left-hand side of the AssignStmt back into the callee. Now, methods can have multiple return statements and as we traverse the reversed interprocedural control-flow graph, there are multiple outgoing edges. We can not reason which return statement is the right one, so we need to taint every return statement's operand in the callee.

Rule 6: An incoming taint $T = x.h^k$ with $k \ge 0$ produces the outflowing taint set $\{r_i.h^k \mid 0 \le i < m\}$.

Unlike at normal flows, we kill all taints not matching any of the rules. In the case of a taint being out of the callee's scope, the Call To Return flow function propagates the taint over the statement.

3.1.3. Return Flow

Taints reaching the end of a method need to be mapped back into the caller. The statement we consider is of the structure $o.m(a_0,...,a_n)$ with $n \in \mathbb{N}$. Again, a_i denotes the *i*-th argument, p_i the *i*-th parameter and c the class instance.

The first rule is the counterpart rule 1 and 2 of Call Flow⁷ and map all parameters back into the caller. In contrast to the Call Flow, we also map primitives and strings back into the caller. When a taint reaches the end of a method in the backward interprocedural control-flow graph, it is actually at the start of the method. At the start of a method, the contents of a tainted parameter were copied from the caller. Thus we taint the argument in the caller.

Rule 1: An incoming taint $T = p_i . h^k$ with $k \ge 0 \land 0 \le i \le n$ produces the outflowing taint set $\{a_i . h^k\}$.

The *this* reference also needs to be mapped back into the caller.

Rule 2: An incoming taint $T = this_c.h^k$ with $k \ge 0$ produces the outflowing taint set $\{o.h^k\}$.

Rule 3: An incoming taint $T = this_c.*$ with $k \ge 0$ produces the outflowing taint set $\{o.*\}.$

Tainted static fields are also mapped back. As already written in the corresponding rule 5 of Call flow, the taints is untouched.

Rule 4: An incoming taint $T = S.h^k$ with $k \ge 0$ produces the outflowing taint set $\{T\}$.

Again, taints not matching any rule are killed. For example, this kills taints, which are not in the caller's scope, when returning from a method.

⁷Note that if k can be 0, the wildcard also works.

3.1.4. CallToReturn Flow

The statement structure is $o.m(a_0,...,a_n)$ with $n \in \mathbb{N}$. a_i denotes the *i*-th argument.

A taint is independent of a callee if it is not static and neither matches an argument nor the base object the method is called on. Such a taint is not matched inside Call Flow and needs to be propagated over the call statement.

Rule 1: An incoming taint $x.h^k$ with $k \ge 0 \land (\forall i \in [0, n] \cap \mathbb{N} : a_i \ne x) \land x \ne o \land x \notin Static Variables produces the outflowing taint set <math>\{T\}$.

Now, consider again the left side of Figure 3.1. In line 3, the str taint is in the kill set of Call Flow because the callee can not be responsible for the tainted variable in the caller. Nevertheless, the taint is still valid after the call. As we want to preserve the taint, we need to propagate the taint over the call statement in such cases.

Rule 2: An incoming taint $T = a_i$ with $0 \le i \le n$ produces the outflowing taint set $\{T\}$.

Like in Call and Return Flow, we also kill taints that do not match any of these rules.

3.2. Runtime of the Data Flow Analysis

IFDS has a worst-case time complexity of $O(|E|\cdot|D|^3)$. |E| is the number of observed edges in the control-flow graph and |D| is the number of observed domain elements by the IFDS analysis. Consequently, the complexity highly depends on the analyzed app and the location of the sources or sinks, depending on the analysis direction. Therefore it is not possible to deduce a general advantage for any direction. Nevertheless, there are certain cases where one direction is favorable, which we discuss in the following paragraphs.

We decide favorably based on the number of taint propagations, i.e., the exploded supergraphs observed edges. They correlate to the runtime and depend on two factors: taints' lifetime and the number of taints. In the following paragraphs, we show examples where the analysis direction influences both factors. After that, we discuss clues suitable for an apriori decision on the direction.

First, we take a look at the is the branching factor. The branching factor describes the number of outgoing edges from a node. A smaller branching factor is favorable. Consider a binary operator expression such as int c = a + b; Backward, we can not argue which

```
String returnParam(int i, String s1, String s2, String s3) {
 2
        if (i == 1)
 3
            return s1;
 4
        else if (i == 2)
 5
            return s2;
 6
        else if (i == 3)
 7
            return s3:
 8
        else
 9
            return "default";
10 }
```

Figure 3.2.: Call Flow Rule 6 Example

operand is responsible for the tainted output and thus proceed with both operands tainted. The same restriction is present in rule 6 of Call Flow which describes how the returned value is mapped back into the callee. This time the branching factor can be even larger. For example, in Figure 3.2 is a method that conditionally returns one of its parameters and is part of the leak path. Let us assume the returned value of a call to returnParam() is tainted. Backward, every returned operand is tainted and later on mapped according to Return Flow rule 2 back into the caller. The effect gets apparent when looking at the method summary. The IFDS algorithm ends up with a summary $retVal \rightarrow \{s1, s2, s3\}$. Forward, a tainted parameter is mapped into the callee and later on returned to the caller resulting in three possible summaries $s1 \rightarrow \{retVal, s1\}$, $s2 \rightarrow \{retVal, s2\}$ or $s3 \rightarrow \{retVal, s3\}$. Such a case favors the forward analysis.

In contrast, a strict right-to-left flow favors backward analysis as taints are killed more often due to a stricter overwrite rule. In Figure 3.3 is such a right-to-left flow displayed. Forward, the right-hand side is always kept alive because it still holds the tainted value below the statement and could be leaked. When traversing a right-to-left flow backward, the left side is always killed. A visited statement is the update responsible for tainting, leading to a branching factor of 1 and a shorter lifetime per taint.

A prominent real-world example of a right-to-left order is Java's StringBuilder. The implementations of append() and insert() return the this instance to allow for easy chaining of multiple calls. Consider the corresponding Jimple code in Figure 3.4. Soot does not reuse the local variables when translating JVM bytecode to Jimple⁸. Although all locals from \$stack9 to \$stack15 refer to the same object, the forward analysis can

⁸Locals are reused when converting Dalvik bytecode to Jimple.

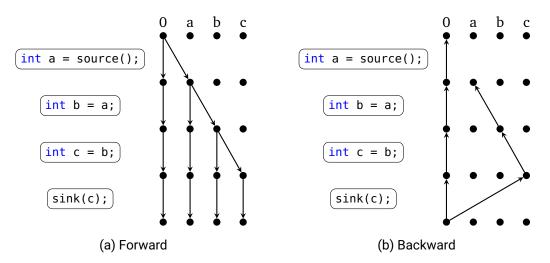

Figure 3.3.: Right-to-Left Order

not kill any of those. In a simple view, our backward analysis has a huge advantage here. However, when we also consider aliases, the advantage is weakened by the aliasing queries. Nevertheless, because the Java compiler internally transforms non-constant string concatenation into a StringBuilder, StringBuilder objects are present in nearly every JVM-based program.

We already briefly mentioned the global scope of static field taints in the last section. Hence, unless the static taint is overwritten, it traverses the whole interprocedural control-flow graph. This obviously creates many unneccessary edges. FlowDroid already applies an optimization and looks ahead to skip methods in which the static field is not used. Still, the long lifetime stays an issue for real-world application and the direction can not generally change this issue [3].

We discussed the complexity based on the taint propagations. However, they are only known after the analysis. Now, it would be beneficial to decide which direction is the best before analyzing an app. An obvious choice for a clue would be the ratio of sources and sinks. If one is much less than the other, we could argue less taints to start with should also lower the taint propagations. Sadly, it is not as easy to generalize the statement to less starting taints means less runtime. Arzt's evaluation of FlowDroid has shown no correlation between the number of sources and the runtime in FlowDroid[3]. This result indicates that the observed statements have way more influence on the number of taint propagations balancing out the initial advantage. Even though the starting taints possibly

```
1 StringBuilder sb = new StringBuilder();
2 sb = sb.append("DeviceID: ").append(id).append("\n IMEI: ")
3
       .append(imei).append("\n ISMI: ").append(imsi);
                                         (a) Java
1 $stack9 = new java.lang.StringBuilder;
2 specialinvoke $stack9.<java.lang.StringBuilder: void <init>()>();
3 $stack10 = virtualinvoke $stack9.<java.lang.StringBuilder:</pre>

    java.lang.StringBuilder append(java.lang.String)>("My device id is ");
4 $stack11 = virtualinvoke $stack10.<java.lang.StringBuilder:

    java.lang.StringBuilder append(java.lang.String)>($stack6);

5 $stack12 = virtualinvoke $stack11.<java.lang.StringBuilder:</pre>

    java.lang.StringBuilder append(java.lang.String)>(",my IMEI is ");

6 $stack13 = virtualinvoke $stack12.<java.lang.StringBuilder:</pre>

    java.lang.StringBuilder append(int)>($stack7);
7 $stack14 = virtualinvoke $stack13.<java.lang.StringBuilder:</pre>
       \hookrightarrow java.lang.StringBuilder append(java.lang.String)>(" and my IMSI is ");
8 $stack15 = virtualinvoke $stack14.<java.lang.StringBuilder:</pre>

    java.lang.StringBuilder append(int)>($stack8);
                                        (b) Jimple
```

Figure 3.4.: StringBuilder example

do not correlate with the runtime, whenever there is a tiny number of sinks but hundreds of sources, the backward analysis should perform better. Likewise, Lerch et al. claim in their work that a magnificent smaller amount of sinks than sources are advantageous for a backward-directed search [23].

The choice on the direction might also be useful for special analysis applications. Think of a case where sanitization methods⁹ are in use. Depending on the use case, it might be possible to deduce the proximity between sanitization methods and sources or sinks. Whenever this is possible, there should be a clear favorite for one direction due to the taints' lower lifetime.

 $^{^9\}mathrm{Sanitization}$ methods are run against user input to ensure the input is safe to be processed.

4. Implementation

This chapter describes the details of our backward-directed implementation and how we integrated it into FLowDroid.

4.1. Integration

First, we needed a backward interprocedural control-flow graph. FLOWDROID already contained one for the on-demand aliasing and it just needed some small extensions. For example, implementing the notifyMethodChanged() method for the use inside StubDroid. Next, we need to introduce unconditional taints at sinks and check for the matching access paths at sources. The methods for retrieving sources and sinks from a Source Sink Manager have different signatures because, in a forward analysis, access paths only have to match at sinks. We added the interface IReversibleSourceSinkManager extending the ISourceSinkManager. It enforces two additional methods:

- SourceInfo getInverseSinkInfo(Stmt sCallSite, InfoflowManager manager)
- SinkInfo getInverseSourceInfo(Stmt sCallSite, InfoflowManager manager, AccessPath ap)

getInverseSinkInfo() returns the necessary information for introducing unconditional taints at sinks, while getInverseSourceInfo() also matches the access paths at sources. All source sink managers needed for the data flow analysis now implement the corresponding interface. Note that reversible source sink managers currently do not support the one-source-at-a-time mode.

For the core flow functions, we created two new classes implementing IInfoflowProblem. BackwardsInfoflowProblem implements the flow functions described in section 3.1. We

also refer to this as the main analysis or infoflow analysis¹. The flow functions for additional language features are sourced out into rules which are informally described in section 4.3. The second class is BackwardsAliasProblem which is the on-demand forward alias analysis. We describe the on-demand aliasing in greater detail in section 4.2.

After the analysis, the path builder constructs a path out of the leaked taint and its predecessors. Because the path builder expects a forward-built taint chain, the path ends up being the wrong way round. To hide the fact that we internally searched backward, we also created a BackwardsInfoflowResults extending InfoflowResults. The implementation is quite simple. It overwrites only the addResult() implementations used by the path builder to save the results and swaps the start and end. If full path reconstruction is enabled, it also reverses the path in between.

4.2. Flow-Sensitive Alias Analysis

FLOWDROID offers multiple aliasing strategies. In this work, we focus on flow-sensitive alias analysis. The analysis is formulated as another IFDS problem. Basically, it is a forward-directed IFDS analysis using flow function with aliasing rules. The main analysis invokes the alias analysis on-demand when it discovers an alias. The alias analysis runs independent from the main analysis and later injects found aliases into the main analysis.

Note that pointer analysis itself is a non-distributive problem [3, 36]. Nonetheless, the alias analysis is encoded in IFDS and we deliberately accept the possibly imprecise results due to the overapproximation. Not using the intertwined alias analysis is too imprecise and the cases of overapproximation are rare in practice [3].

Handover between the analyses The main analysis discovers aliases at assignments. Consider Figure 4.1 where two different cases are displayed. On the left is a normal flow according to rule 1. In line 2, the in taint a.str produces the outcoming taint b.str. Because the assignment type is a heap type, the backward analysis now recognizes that it possibly missed updates to b.str below of line 2. It invokes the alias analysis with b.str. On the right is a normal flow according to rule 3. This time the assignment in line 2 is swapped. The main analysis leaves the incoming taint b.str untouched but notices a aliases b below line 2, hence invoking the alias analysis with a.str.

¹The term information flow analysis is sometimes used interchangeably with taint analysis. Others use it to describe taint analyses which also support implicit flows [23].

```
1
      void aliasRule1() {
                                                   1
                                                      void aliasRule3() {
                                                   2
   2
           A a = b;
                                                          A a = b;
   3
                                                   3
           b.str = source();
                                                          a.str = source();
                                                   4
   4
           sink(a.str);
                                                          sink(b.str);
                                                   5 }
   5
      }
(a) Example for alias analysis initiated by
```

rule 1

(b) Example for alias analysis initiated by rule 3

Figure 4.1.: Normal flow Aliasing examples

```
1 void turnStmtNeeded() {
2     A a = b;
3     String str = b.str;
4     a.str = source();
5     sink(str);
6 }
```

Figure 4.2.: Aliasing example with turn unit

The alias analysis searches for missed updates. If the analysis found an update, e.g., the taint is on the left side of the assignment, the analysis injects the edge to the statement with the taint into the main analysis' worklist. Consider again Figure 4.1a. In line 3, the alias analysis encounters the tainted b.str on the left side. At this point, b.str gets handed back to the main analysis, following the missed update to find a possible leak. In this case, the leak happens right away.

Maintaining Flow Sensitivity Arzt solved this in the existing forward implementation using an activation unit. This statement marks the update at which the alias gets tainted and can leak at sinks [3]. This concept does not work for our backward implementation as our alias analysis traverses forward where the taint is already valid. Thus we introduce the turn unit. The turn unit holds the last non-aliasing assignment. When a taint reaches its turn unit in the aliasing analysis, the analysis kills the taint. Consider Figure 4.2. The introduced taint str in line 6 also initially has line 6 as a turn unit. In line 3, a non-aliasing assignment happens, hence the turn unit is updated. In line 2, b.str is tainted and the alias analysis is invoked with a.str. Without the turn unit, the taint would pass line 3. Further in line 4, the taint is handed to the main analysis. The main analysis then reports

```
1 void foo() {
2     // In: {o1.str}
3     bar(o1);
4
5     // In: {o2.str}
6     bar(o2);
7 }
```

Figure 4.3.: Summaries And Turn Units

a leak. With the turn unit in place, the alias analysis kills the taint in line 4, preventing the false positive.

The turn unit is a new field in the Abstraction class, which is representing a taint. A possible drawback of the backward analysis could be the reusability of the IFDS summaries. Because the turn unit is part of the taint, IFDS treats equal taints with different turn units as if they have a different context. Consider Figure 4.3 within the alias analysis. Let us assume IFDS already returned from the call bar(o1) and created the summary for this context. Later, the analysis observes the same access path with the same context but a different turn unit. Now, IDFS can not apply the summary from bar(o1). If turn unit of o1 is inside the callee or one of the transitive callees but the turn unit of o2 is not, we would effectively lose the flow sensitivity as the taint is wrongfully killed. In the reverse case, we would also lose the flow sensitivity because, this time, the turn unit is ignored.

4.3. Rules

Flow functions can get quite large, complicated to understand and hard to maintain [24]. To counteract this, FLOWDROID outsources certain features into rules. These rules also implement the four flow functions and are applied in the main analysis's corresponding flow function. In this section, we describe our implementation and informally state the rule behavior.

4.3.1. Source & Sink Propagation Rule

In backward analysis, sources act like sinks and vice versa. Thus, the Source Propagation Rule records taints flowing into sources and the Sink Propagation Rule unconditionally introduces taints at sinks requiring an IReversibleSourceSinkManager.

Notably, the default handling of sources assumes the return value to be tainted. Only if the return value is ignored or the method has no return value, the base object is assumed to be tainted. While at sinks the base object and parameters are leaked by default [3]. Thus, starting at sinks might result in more taints per statement. We did not notice an impact on the performance in the development phase but the test cases are fairly simple, so the base object creation is often right before the sink call. Also, we do not think this impacts the real-world performance of the backward analysis because Arzt evaluation of the forward implementation showed no correlation between runtime and source count [3]. Whether this is true is sorted out in the evaluation in section 6.2.

4.3.2. Backwards Array Propagation Rule

In FlowDroid, array taints are overapproximated by only distinguishing contents and length but not elements. Meaning if one element of an array is tainted, FlowDroid considers all elements tainted. Indices are often computed at runtime and thus not available for a static analysis without applying another analysis beforehand. Hence, the approximation is not as severe because we could only track constant indices without large overhead regardless. Furthermore, distinguishing elements would increase the domain even more, subsequently increasing the runtime [3].

The Array Propagation Rule handles ArrayNewExpr, LengthExpr and ArrayRef on the right-hand side.

- Array Rule 1: If the left side's length is tainted and the right side is an ArrayNewExpr, the outcoming taint is the size local of the ArrayNewExpr.
- Array Rule 2: If the left side is tainted and the right side is a LengthExpr, the outcoming taint is the operand of the LengthExpr with only its length tainted.
- **Array Rule 3:** If the left side is tainted and the right side is an ArrayRef, the outcoming taint is the array base with only its content tainted.

The overapproximation of arrays also implies that array taints can not be killed if the left side is an ArrayRef.

4.3.3. Backwards Exception Propagation Rule

The backwards analysis first finds a catch statement \$someVar := @caughtexception. If the left side matches, it sets an exception flag at the taint and propagates it onwards. The subsequent propagation then finds the corresponding throw statement.

- Exception Rule 1: On a caught exception expression, derive a new taint with an exception flag set.
- Exception Rule 2: If a taint with the exception flag set occurs at a ThrowStmt, derive taint the operand of the ThrowStmt.

The second rule is present in Call and Normal Flow because the throw statement can be inside the same method or in a callee.

4.3.4. Backwards Wrapper Propagation Rule

The implementation of this rule is similar to the existing implementation. A tainted returned value also needs to be passed into the taint wrapper because of the backward direction. The rule calls getInverseTaints() and thus requires the taint wrapper to implement the IReversibleTaintWrapper interface.

Additionally, we added an optimization to the taint wrapper rule. Recall section 3.2 where we explained our backward implementation benefits from a right-to-left order. The StringBuilder however can alias and the alias search offsets the advantage. We use the observation that Jimple does not reuse the local variables when compiled from Java bytecode and all locals pointing to the same StringBuilder instance except one are not reused either. Thus, we apply a live variables analysis for the base object between the current statement and the turn unit as a preanalysis. Only if the preanalysis finds an use, the alias analysis is used. The preanalysis needs around $100\mu s$ runtime per query. Based on our observations, it should rarely find an use. We reviewed the optimization using the well-known org.json² library. The library makes use of StringWriter, which internally uses StringBuffer. A StringBuffer has the same chaining in place for the append() and insert() methods. For the test case shown in Figure 4.4, we observed 58 misses and 0 hits while spending 0.0337 seconds in the preanalysis until the analysis found the first flow.

```
1 ic void JSONTest() {
2 String tainted = TelephonyManager.getDeviceId();
3 JSONObject json0 = new JSONObject();
4 json0.put("str", tainted);
5 ConnectionManager cm = new ConnectionManager();
6 cm.publish(json0.toString());
```

Figure 4.4.: JSON Test Code

4.3.5. Backwards Implicit Propagation Rule

Flows which are influenced by a condition are called implicit flows. A common example is a password check. Such a method could return a boolean signifying the password is correct or not. Without implicit flows, the taint analysis would be unable to find the path between the password input and the output action. The semantics of implicit flows in FLOWDROID are that every update flowing into a sink or a sink call inside a conditional branch, even in transitive callees, is considered a leak.

The existing forward-directed implementation derives a wildcard taint³ and propagates it until the conditional branch is left again at the immediate postdominator. This behavior does not scale well because the semantics demand tainting every update and following every call in conditionals leading to many unneccessary taints never reaching a sink. The bad scalability is not an issue specific to FLOWDROID but is present for most analyses providing implicit flows [19].

We also use the wildcard taint but with a different semantic. Backward, the wildcard signifies a conditional update and is propagated further to find the corresponding condition. Thus, the branching factor inside a conditional branch should be lower. To detect a conditional, we push and pop the dominator on the taints. Whenever an update is conducted to a taint carrying a dominator, the wildcard taint is derived. However, it is not that easy to reconstruct the conditional branches while traversing the exploded supergraph. Consider the code in Figure 4.5. We expect from the analysis to find the path from line 2 to line 10. First of all, starting at the sink it is unknown whether a conditional influenced the call to the transitiveSink() method. Also, assuming we created a taint representing the sink call, consider the return edge into foo(). The edge is already inside a conditional branch, thus the dominator is per-definition line 4. We cannot use the dominator as a

³A wildcard taint is an taint without an object or access path but a wildcard appended.

```
1
   void foo() {
2
        int tainted = source();
 3
        if (tainted == 42) {
 4
            x = 0;
 5
            transitiveSink();
 6
        }
7
   }
8
9
   void transitiveSink() {
10
        sink();
11 }
```

Figure 4.5.: Implicit Flow Challenges

indication whether a taint enters a conditional in such cases. Both of those challenges are not a data-flow problem but rather a control-flow graph reachability problem. We extended the backward interprocedural control-flow graph with two methods:

- List<Unit> getConditionalBranchesInterprocedural(Unit unit)
- Unit getConditionalBranchIntraprocedural(Unit unit)

The first one is used for sink calls. It traverses the interprocedural graph using a worklist algorithm to find all possibly reachable conditional statements. We then use those found conditionals to derive sink taints with the correct conditional dominator. The second one is used at return edges and returns the conditional statement if the call site is inside a conditional else null.

4.3.6. Backwards Strong Update Rule

Until now, we always assumed that a taint is only affected if the variable occurs in a statement. However, with aliasing, this gets more complicated. A taint could not match the left side and, thus, is propagated over the statement according to the default rule of normal flow, but the taint is an alias of the left side and should have been killed. Also, we can not just link aliases to taints for such strong updates because that would violate the flow functions' distributiveness property.

Figure 4.6.: Examples of statements being in <clinit>

In this case, FLOWDROID falls back to Soot's must-aliasing analysis. However, the must-aliasing analysis is only intraprocedural. Thus, strong updates split over methods are not detected and produce a false positive.

Backward, the first observed update is the correct one. We treat a must-alias like a regular match:

• **Strong Update Rule**: If the incoming taint must-aliases the left side, then apply the normal flow rules just as if the left side was tainted.

4.3.7. Backwards Clinit Rule

<clinit> is a special method in the JVM and stands for class loader init. The compiler generates the method and calls it implicitly. Examples of statements that get compiled into clinit are in Figure 4.6. The invokation is implicit at the class's initialization phase and is executed at most once for each class⁴. SPARK, the default call graph algorithm of FLOWDROID, overapproximates the <clinit> behavior. It adds an edge to <clinit> at each statement containing a StaticFieldRef, StaticInvokeExpr or NewExpr⁵.

The need for this rule is rooted in the IFDS solver of FLOWDROID. The solver decides whether to use Normal Flow or Call Flow by calling isCallStmt(Unit u) on the interprocedural control-flow graph generated by Soot. Internally, this method calls containsInvokeExpr() on the Unit object. containsInvokeExpr() for AssignStmt only returns true if the right-hand side is an instance of InvokeExpr. Consequently, the

⁴Source: https://docs.oracle.com/javase/specs/jvms/se8/html/jvms-2.html#jvms-2.9 (visited on 17.04.2021)

⁶https://github.com/soot-oss/soot/blob/59931576784b910a7d38f81910b7313aa2feafea/src/main/java/soot/jimple/toolkits/callgraph/OnFlyCallGraphBuilder.java#L969 (visited on 17.04.2021)

calls to <clinit> from AssignStmts with NewExpr or StaticFieldRef on the right side are missed.

The Backwards Clinit Rule manually injects an edge to the <clinit> method in the infoflow solver when appropriate during the analysis. Also, it lessens the overapproximation of SPARK by carefully choosing whether to inject the edge. The rule works as follows:

- Clinit Rule 1: If the tainted static variable is a field of the methods class, do not inject because we will at least encounter a NewExpr of the same class further in the call graph.
- Clinit Rule 2: Else if the tainted static variable matches the StaticFieldRef on the right hand side: Inject the edge because we can not be sure whether we see another edge to <clinit>.
- Clinit Rule 3: Else if the class of the tainted static variable matches the class of the NewExpr: Inject the edge because we can not be sure whether we see another edge to <clinit>.

The behavior is still an overapproximation, of course. A more precise solution would require bookkeeping of every class's last observation equal to the first occurrence in the code.

In the existing implementation, there is no such explicit modelling. As taints are introduced at sources, if the source statement is inside a static initialization like in Figure 4.6a, the propagation starts inside the <clinit> method. Then unbalanced problem handling of the solver propagates the taint into the callers of ClinitClass1 <clinit>. This behavior allows the forward analysis to detect leaks originating from static variable initializations but misses leaks inside static blocks as shown in Figure 4.6b.

4.3.8. Other Rules

Skip System Class Rule and Stop After First K Flows Rule are not direction-dependent. Both are shared with the forwards search and therefore use the existing implementation in FlowDroid.

```
1 char[] tainted = source();
2 StringBuilder sb = new StringBuilder();
3 sb.append(tainted, offset, len);
4 sb.append("untainted");
5 sink(sb.toString());
```

Figure 4.7.: Easy Taint Wrapper Example

4.4. Other Components

4.4.1. Taint Wrappers

FLOWDROID already has an interface IReversibleTaintWrapper for taint wrappers providing inversed summaries. The SummaryTaintWrapper using StubDroid's summaries already implemented this interface. For the EasyTaintWrapper, we contributed the inverse implementation. Its implementation follows simple rules which cover most cases[3]. The rules are inverted to:

- If the return value is tainted, taint the object and the parameters.
- If the base object is tainted, taint all parameters.

Note that these simple rules are disadvantageous for the backward direction the more parameters a method has. Consider the code snippet in Figure 4.7, especially line 3. Forwards, tainted is the incoming taint and the EasyTaintWrapper produces the taint set {tainted, sb}. Backward, the incoming taint is sb and the taint wrapper produces four taints {sb, tainted, offset, len}. Luckily, most methods supported by the EasyTaintWrapper have less than three arguments.

4.4.2. Native Call Handler

The native call handler of FlowDroid handles two methods: System#arraycopy and reflect.Array#newArray. The handling of System#arraycopy is direction-dependent. Thus, we adapted the existing implementation and reversed the logic of System#arraycopy to reflect the analysis direction.

4.4.3. Code Optimizer: AddNOPStmts

Before starting the analysis, FLowDROID applies code optimization to the interprocedural call graph. By default, dead code elimination and within constant value propagation is performed. Those are also applied before backward analysis, but we needed another code optimizer to handle an edge case in backward analysis.

First, consider the static2Test test case in the StatictTestCode class of FLowDroid in Figure 4.8. The method is also the entry point for the analysis, is static and does not have any parameters. The same is true for the source TelephonyManager#getDeviceId. Due to the first condition, static2Test has no identity statements and because of the second condition, there are also no assign statements before the source statement in Jimple. Therefore the source statement is the first statement in the graph. Next, a detail of FLowDroid's IFDS solver is important. The Return and CallToReturn flow function is only applied if a return site is available. When traversing backward, the source statement is the last and thus has no return sites. Now, the taints flowing into source methods are registered in the Call To Return flow function. Altogether, leaks are missed if the source statement is the first statement.

Moving the detection of incoming taints flows into sources from the CallToReturn to the Call flow function was not an option because by default source methods are not visited and changing this would require multiple changes in the existing implementation. Our solution is to add a NOP statement in such cases before the analysis. Due to the entry points being known beforehand, the overhead is negligible.

```
1 public static void static2Test() {
 2
        String tainted = TelephonyManager.getDeviceId();
 3
        ClassWithStatic static1 = new ClassWithStatic();
 4
        static1.setTitle(tainted);
 5
        ClassWithStatic static2 = new ClassWithStatic();
 6
        String alsoTainted = static2.getTitle();
 7
 8
        ConnectionManager cm = new ConnectionManager();
 9
        cm.publish(alsoTainted);
10 }
                                          (a) Java
 1 public static void static2Test() {
        tainted = staticinvoke
            \hookrightarrow <soot.jimple.infoflow.test.android.TelephonyManager:
            \hookrightarrow java.lang.String getDeviceId()>(); // Line 2 in (a)
 3
 4
        // [...]
 6
        virtualinvoke cm.<soot.jimple.infoflow.test.android.ConnectionManager:</pre>
            ⇔ void publish(java.lang.String)>(alsoTainted); // Line 9 in (a)
 7
 8
        return;
 9 }
```

Figure 4.8.: static2Test Code

(b) Jimple

5. Validation

5.1. Unit Tests

FLOWDROID already contains 519 unit tests for the core component. We also validated the backward analysis with these tests. In the following, we briefly explain why tests were left out or did not return the same results.

EasyTaintWrapperTests equalsTest and hashCodeTest are expected to return one leak, but the backward analysis does report no leaks. This difference is related to the EasyTaintWrapper implementation. equals() and hashCode() are exclusive in the EasyTaintWrapper, which means the analysis can skip these methods because the taint wrapper provides a summary for them. The exclusive check happens in the Call Flow function. In both tests, the source is in an exclusive method. The IFDS solver behaves as already observed with <clinit> in subsection 4.3.7 and creates a return flow for an unbalanced problem; while going backward, the exclusive check kills the taint in the Call Flow function and applies the summary unaware of the override. We marked those two tests forwards-specific and created two equivalent backward-specific tests with sinks inside the equals() or hashCode() method with one expected leak.

HeapTestPtsAliasing We focused in this work on flow-sensitive aliasing, which is the default aliasing strategy of FlowDroid. Other aliasing strategies are left for future work.

5.2. DroidBench

DROIDBENCH is a test suite to evaluate data flow analysis tools targeting the Android ecosystem. It originated from the initial work on FlowDroid to assess it in comparison

to other tools [6]. The latest development version 3 includes 190 test cases¹. We used the newest commit on the develop branch at the time of writing² to validate our implementation. ³ We aim to achieve similar results as FLOWDROID's existing forward implementation.

5.2.1. Configuration

For the validation, we ran FlowDroid with the Android module's default configuration using the EasyTaintWrapper as the taint wrapper. The configuration summary is in Table 5.1.

Option	Value
Array Size Tainting	disabled
Inspect Sources & Sinks	disabled
Static Field Tracking	enabled
Ignore Flows in System Packages	enabled
Exclude Soot Library Classes	enabled
Timeout	-
Taint Wrapper	EasyTaintWrapper

Table 5.1.: Real World Apps Configuration

We only used a subset of DroidBench's tests to validate our results. Dynamic Code Loading, Self Modification, Unreachable Code and Native Code are all not supported by FlowDroid. The first three are all call-graph related and the latter is not supported because FlowDroid has no Android native call handler for now. Also, Inter Component Communication (ICC), Reflection Inter Component Communication and Inter App Communication were left out because the ICC module is - at the time of this work - not maintained anymore. All of the tests stated above are flow function independent. If FlowDroid gets support for those features in the future, they should also work in backward analysis.

³Commit ddbd50c

5.2.2. Results

The complete overview of the results is in Table 5.2. \odot denotes true positive, \star false positive and \bigcirc false negative. If a row is empty, the test expects no leaks and also none were found.

Our backward-directed implementation yields nearly the same result as the existing forward implementation, with one missed leak more than the baseline. We achieve a F1 measure of 0.89 equally to the baseline.

Table 5.2.: DroidBench Validation Results

5.2.3. Results Explanation

The analyses only differ in StaticTests#StaticInitialization1 where we do not miss the leak. As all StaticInitialization tests depend on the <clinit> behavior modeling, we decided to explain all three even though only StaticInitialization1 is different.

StaticInitialization 1 differs between forward and backward analysis. Backward reports one leak due to the explicit modeling of <clinit> edges instead of relying on SPARK. Recall subsection 4.3.7, leaks inside static blocks are missed in the forward analysis. This test case is quite similar to Figure 4.6b, and therefore, only the backward analysis reports the leak. The Clinit Rule could also be ported to the forward analysis but a larger overapproximation. Unlike backward, there is no guarantee that there will be another edge to <clinit> if the statement is in the same class as the <clinit> method. Thus, it inherits the entire overapproximation from the SPARK call-graph algorithm.

StaticInitialization2 yields the same result but because of different reasons. The test assigns a tainted value to a static field in the static initializer. Again, recall subsection 4.3.7.

Backward, the clinit rule takes care of visiting the <clinit> edge while forwards the followReturnsPastSeeds option of the IFDS solver is responsible.

StaticInitialization3's leak is missed despite the explicit modeling of clinit. The code is provided in Figure 5.1. The MainActivity is using the singleton pattern and thus has a static field v referring to its instance. The source statement is inside the Test class's static block using the singleton to access the instance field s. The taint is now introduced at the sink and refers to the field through the this instance. When we visit line 13, the <clinit> edge is not taken due to the taint being an instance field. Line 12 kills the taint and stops the analysis as there is no taint to propagate anymore. We never get to see the statement where the static field v aliases this. The false negative is a limitation of the alias handling.

5.2.4. Improvements From The Summary Taint Wrapper

We briefly explained the simple but not always precise rules of the EasyTaintWrapper in subsection 4.4.1. Using StubDroid's more precise summaries yields even better results for both directions. The false positives in the test cases BroadcastReceiverLifecycle2 and SharedPreferenceChanged1 are gone and the leak in Serialization1 is found.

```
1 \quad \hbox{public class MainActivity extends Activity } \{
 2
         public static MainActivity v;
 3
        public String s;
 4
 5
        @Override
 6
        protected void onCreate(Bundle savedInstanceState) {
 7
             v = this;
 8
 9
             super.onCreate(savedInstanceState);
10
             setContentView(R.layout.activity_main);
11
12
             s = ""; // T={}
13
             Test t = new Test(); // T={this.s}
14
             Log.i("DroidBench", s); // T={this.s}
15
        }
16 }
17
18 class Test {
19
        static {
20
             TelephonyManager mgr = (TelephonyManager)
                 \hookrightarrow \texttt{MainActivity.v.getSystemService}(\texttt{Activity.TELEPHONY\_SERVICE});
21
             MainActivity.v.s = mgr.getDeviceId(); // source
22
        }
23 }
```

Figure 5.1.: StaticInitialization3 code

6. Performance Evaluation

In the last chapter, we have shown that our implementation has the necessary soundness to be viable and yields the expected results. We now evaluate our implementation against the existing implementation in FLOWDROID.

6.1. DroidBench

We already introduced Droidench in section 5.2 to validate the soundness of our backward-directed implementation. In this section, we focus on the performance in comparison to the existing forward-directed implementation in FlowDroid.

DroidBench has the advantage that all apps are crafted explicitly for benchmarking taint analysis. So, most tests only contain a single-figure number of sources and sinks. Also, the number of sources and sinks are often equal or differ by one to test whether the tool can differentiate something. These simplify the comparison between both analysis directions as neither one has an initial disadvantage.

Most test cases are small enough to be analyzed in sub-two seconds on an average four-core desktop CPU from 2012. Our test environment is not isolated, so background tasks and the process scheduler can affect the runtime. Together with the variance of the unisolated testing environment, the short runtime renders the runtime unusable as a comparison point. In contrast, edge propagations are deterministic¹ and correlate with the runtime. Thus, we only use the number of propagations to compare both implementations.

The configuration is the same as described in subsection 5.2.1.

¹This is only true if there are enough resources. FLowDROID tries to gracefully terminate when running low on memory. Also, timeouts result in a non-reproducible number of edge propagations.

6.1.1. Results

The full results are listed in Table 6.1. When rows only contain hyphens, the IFDS analysis did not start, e.g., because no sink is in the reachable code. #I denotes the number of edge propagations inside the infoflow analysis and #A the number of edge propagations inside the alias analysis. We calculated the absolute difference with the existing implementation as the reference: $Result_B - Result_F$. The relative difference is calculated similarly: $\frac{TotalDifference}{|\#I_F + \#A_F|}$. Hence, negative values signify the backward analysis performed better.

On average, our implementation needs more edge propagations to finish the analysis. Even though for explicit flows the backward analysis needs fewer propagations in the infoflow analysis, it then suffers from more encountered aliases. If we look at it on a per-test basis, there are not many test cases where both perform identically. Instead, dependent on the specific test case, the relative difference is between -1 and 1. However, we did not expect cases that let the edge propagations of our implementation explode up to a factor of 100, as seen in LifecycleTest#BroadcastReceiverLifecycle3. In contrast, the existing forward implementation has a maximum relative difference of -0.95.

Table 6.1.: DroidBench Performance Evaluation Results

6.1.2. Result Explanation

We define tests with a relative difference greater than 10 as worth investigating. In the following, we explain why our implementation performed worse than expected.

PrivateDataLeak3 This test contains two sinks and one source. The tainted data is written to a file, later read from the file and then leaked. FLOWDROID does not support tracking taints over files, so it only finds a leak from source to file write but misses the leak from file read to send SMS. Due to EasyTaintWrapper's simplicity, overtainting happens in the backward direction. When FileInputStream fis = openFileInput("out.txt"); is called with fis tainted, EasyTaintWrapper also taints the base object - the MainActivity in this case. As the MainActivity has an enormous scope, the taint has a long lifetime and many other taints could derive from this taint. This taint explains the relative difference of 17.68. Using the more precise SummaryTaintWrapper, the edges reduce to (51, 16) and a relative difference of 2.53, which is more reasonable. It is still higher because of the second sink.

MultiHandlers1 Two LocationListeners are registered in different activities. In both activities, an instance field is a parameter of a sink. So there are two possible paths where something could be leaked. The LocationListener does not call any source on the first path, while the second path has an empty setter method killing the taint. For the first path, the backward analysis has to propagate the taint into the LocationListener to notice that this is a dead-end while the forward's search does not even start there. For the second path, the backward analysis seems to suffer because it starts at an instance field taint with a larger scope than a local variable.

BroadcastReceiverLifecycle3 The test contains five sinks but only one source. If we only consider the leak path, both implementations perform equally. The four other sinks are responsible for the overhead on edge propagations.

Reflection6 The reflective call site has multiple possible callees in the interprocedural control-flow graph. Backward all of these callees are visited, of which only one contains a source statement. Forward, the taint is introduced in the callee at the source and just one return site needs to be processed.

A Note On Implicit Flows All implicit flow tests and the IMEI1 test need the implicit flow rule to find the leaks. In those test cases, our implementation does not stand a chance. We especially want to highlight the "every sink call influenced by conditional" semantics here. This semantic forces us to derive an empty taint for every conditional that is theoretically reachable from a sink. Beyond, we also taint the base object without any fields at every sink to detect a possible conditional object instantiation. Even in simple test cases such as ImplicitFlow4 this results in 10 additional taints per sink. Important to note is also that the prior computation of reachable conditionals is not represented in the edge propagations. We thus conclude that it is probably better to live without a backward-directed implicit data flow analysis.

6.1.3. Using A More Precise Taint Wrapper

We noticed the overtainting in PrivateDataLeak3 is caused by the EasyTaintWrapper. Thus, we now look at how using the SummaryTaintWrapper influences the edge propagations. The full results are in Table 6.2. In the table, we take the EasyTaintWrapper as the reference and compare it against the SummaryTaintWrapper on our implementation. The structure of the table is as in the last subsection.

As we already described, PrivateDataLeak3 benefits from the more precise taint wrapper. Similarly, many other test cases also benefit. Others, especially Serialization1 have more edge propagations because the SummaryTaintWrapper has a summary for a method which the EasyTaintWrapper does not handle² resulting in a premature kill of a taint. Even with Serialization1 included in the average, the SummaryTaintWrapper needs fewer total edge propagations. Excluding it also equals out the relative difference. Altogether, the SummaryTaintWrapper should be the default choice for real-world applications because it is more precise without compromising on the edge propagations.

Test Case	Easy	TW	Summ	SummaryTW		Difference			
	#I	#A	#I	#A	#I	#A	Total	Relative	
AliasingTest

		Andro	idSpecifi	cTest					

²The EasyTaintWrapper contains a list of supported classes. Every method from those classes is excluded from the analysis, regardless of the method being in the list of the handled methods.

Table 6.2.: DROIDBENCH Evaluation with Summary Taint Wrapper

6.2. Real World Apps

6.2.1. Configuration

Our test machine is equipped with four Intel Xeon E5-4650 and 1 TB of RAM. We limited the JVM to 50 GB RAM and FlowDroid on 16 threads per instance. We ran four instances in parallel to ensure a one-to-one mapping between CPU threads and FlowDroid threads. Note that the test machine is a shared system, but we made sure there are always enough resources for our evaluation available. Still, background services might influence the performance of a single run. To stamp out this factor, we ran each app three times with a distance of time³. If there were outliers⁴, we repeated the run. ⁵ Some runs did not comply with our outlier norm even after we ran them multiple times, but this only concerns 9 out of 600 runs.

We also measured the memory usage of both implementations. Using the memory amount reported by the JVM is not precise because the JVM prefers to take up free memory before running the garbage collector [3]. We borrowed the memory evaluation tool from CleanDroid, which internally depends on a memory calculation tool from Twitter⁶. The memory evaluation tool measures the size of the exploded supergraph in 15 seconds intervals [4]. Because we do not want to pollute the measured data flow time with the memory evaluation tool's latency, the memory measuring runs were run independently of the time measuring runs. The memory sampling also takes up memory and because our test system has enough memory available, we bumped the maximum heap size up to 100GB, effectively eliminating memory timeouts.

³The time distance between each run is at least the elapsed time from the analysis of the remaining 199 apps.

 $^{^5}$ Outliers are runs with at least 25% difference to the median run and a minimum of 5 seconds absolute difference

Timeout	10 minutes
Taint Wrapper	SummaryTaintWrapper

Table 6.3.: Real World Apps Configuration

For this evaluation, we chose to use a non-default configuration of FLOWDROID. First, we disabled static field tracking due to the global scope as described in section 3.2. Next, instead of the EasyTaintWrapper, we use the SummaryTaintWrapper, which utilizes StubDroid. We set the timeout for the data flow analysis to 10 minutes⁷. The call graph generation was limited to 180 seconds and the call graphs were serialized before, so every run was on the same call graph. The configuration summary is in Table 6.3.

We did not use the full sources and sinks list included in FlowDroid because such would result in hundreds of sources and sinks per app and probably a long runtime. Instead, we chose to analyze which sensitive and possibly user-identifying data is sent out to the internet. As we want to compare the forwards and backward implementation, it is also essential to not put one at a disadvantage. We opted for a 2:1 ratio of sources to sinks. This decision is based on the results of SuSi, a tool to automatically find sources and sinks in the Android framework [31]. Their extracted list of sources and sinks contains roughly 2.17 times more sources than sinks. The list of sources and sinks used in this evaluation is in Table 6.4 and Table 6.5.

We used FlowDroid's forward implementation on the to that date latest upstream commit⁸ from the develop branch for the point of comparison. The backward implementation ran on our latest commit⁹ at that time, with all changes from the upstream merged into.

We chose 200 apps randomly out of a Google Playstore dump from 2021 containing over

⁷A timeout in FlowDroid prevents processing new edges but lets the solver finish the current edge propagation. Thus, some apps may have a data flow time of above 600 seconds.

⁸The latest upstream commit was at that time b436733fc4a5130dfe4ce8ddb3f76fd374e9a487.

⁹Our latest commit was 87bf33ba40ef8b4fb25f33439d887ebc98c2c184. Note that we found some bugs during the real-world evaluation and later on fixed some edge cases in the analysis. All fixes should not influence the runtime in a bad way.

Table 6.5.: Sinks for Real World Apps Evaluation

6000 apps for our evaluation set. Out of 200 apps, 60 apps do not have any sources or sinks and thus, the analysis did not start. For six apps, the analysis aborted with errors on at least one run. All thrown exceptions happened outside of FlowDroid. We are left with 134 apps for which both implementations completed all runs without errors. The full list is appended to this work in Table A.1.

6.2.2. Time Evaluation

In general, the individual apps' runtimes were far apart from each other. We had many apps with a single-digit analysis time and on the other side, we also found many apps that triggered a timeout or were close to triggering one. In between those extrema are only a few apps. Recall that we set a soft limit on the runtime at 600 seconds. The reference forward runs have a standard deviation of 209 seconds and the runs of our implementation has 277 seconds standard deviation. It is essential to keep this in mind when interpreting the results.

We first begin with an overview of the results. Table 6.6 shows the results, including timeouts. Notably, the backward analysis had 20% less time timeouts than the forward analysis. In return, it seems a bit more memory-hungry with 3.63% more memory timeouts. We conducted a t-test to check the significance of those differences with the null hypothesis of equal average expected values. The p-value for the memory timeouts is 0.156, thus being insignificant. A t-test over the runtime yielded a p-value of 0.00036, meaning the

	Forward				
Metric	Avg	Median	P_{85}

Memory Timeouts			6.62%
Time Timeouts			59.56%

Table 6.6.: Results With Timeouts

advantage for our implementation is significant. We cover the memory consumption extensively in the following subsection and focus on the time for now. Interestingly, the propagated edges along the same interprocedural call graph are of the same order of magnitude. Also, the 85th percentile runtime is nearly equal and the median is equal. However, claims based on the runtime and edges with timeouts are only possible to a limited extent because the timeout highly influences both values.

Next, we only consider the runs without any timeouts in Table 6.7. This time, the relation between backward infoflow edges and forward alias edges is present to a lesser extent. More significant, backward needed fewer propagations in average and in the 85th percentile. This fact is also represented in the runtimes. The average runtime is half of the existing implementation. Though because of the diverse data, the average is not convincing. The median is equally at zero for both. This is partly based on FlowDroid's measuring, where it only measures the time in seconds and rounds it down. Thus, all runs with a runtime of zero seconds did terminate in less than 1 second. In the 85th percentile, more significant given our data set, the backward analysis needs 68.8 seconds less.

A knowledgeable reader might have noticed the results in Table 6.6 are worse than in

	Forward

Table 6.7.: Results without Timeouts

previous publications where FlowDroid was evaluated [3, 4]. We want to emphasize that none of our changes influenced the reference runs in a bad way as we used the upstream version without a single line changed to conduct the first run¹⁰. The existing implementation suffers as ours, so we suspect it partly depends on an unfortunately drawn app set and further development in the call graph generation leading to more possible edges.

With that out of the way, let us look at the results in greater detail. We now compare the analysis on a per-app basis. The histogram is in Figure 6.1. We compiled the delta data flow time of the analyses per app, calculated as in the last section with the forward implementation being the reference: $t_{Backward} - t_{Forward}$. Hence, negative values represent that our implementation performed better. The delta on the x-axis is given in seconds and the frequency on the y-axis in the number of apps. The bins always span over 50 seconds. The graph shows a large number of apps around 0 with a slight bias towards the forward implementation. Equivalent to the distribution of the data flow times, there are only few deltas in the range from ± 100 to ± 500 . More interestingly, there are significantly more apps around -600 than around 600. Recall, the timeout is set to 600s. So, our implementation terminates nearly instantaneous in some cases on which the forward analysis times out. As expected, there is no general advantage for a direction. Instead,

¹⁰We found some exceptions in the upstream project while evaluating, so we switched to our version with the fixes included after the first run. This change did not yield the results any worse than before.

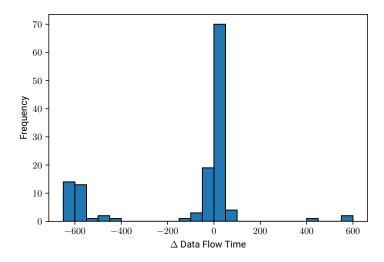

Figure 6.1.: Histogram of the Delta Data Flow Time

we observe a per-app advantage in around 60% of the test set, while for the rest, the performance is similar.

We confirmed that the right direction choice could speed up the analysis by a magnificent amount. To take advantage of the favorable direction, we now investigate the correlating conditions for the advantageous direction. Most straightforward would be a correlation between the difference of source and sink count and the data flow time. In Figure 6.2c are two graphs with the ratio of sources and sinks ($\frac{Sinks-Sources}{Sources}$) on the x-axis and the data flow time in seconds on the y-axis. The left graph is always the forward implementation and the right graph is our implementation. Blue dots represent apps without a timeout, orange a time timeout and red a memory timeout. Intuitively, a negative ratio should put our implementation at an advantage. The graphs show no correlation between the ratio and the runtime, neither forward nor backward. We also included the forward data flow time by sources and the backward data flow time by sinks in Figure 6.2a and Figure 6.2b. The number of sinks backward and the number of sources forward do not influence the runtime. So we can confirm Arzt's evaluation[3] as there is no correlation between sources and the forward runtime in our app set. Parallel to this observation, the sink count does not influence the backward runtime. The sink count for forward and the source count for backward can not influence the runtime as they neither influence the edge propagations.

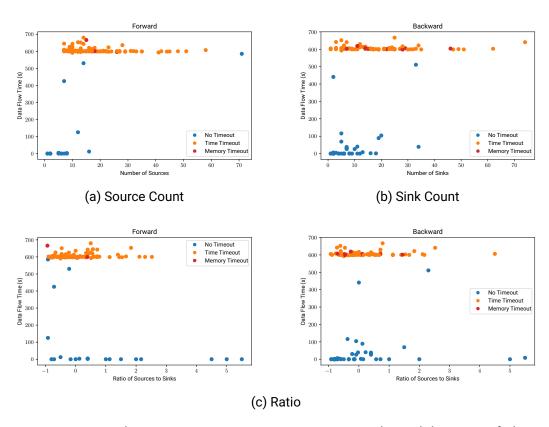

Figure 6.2.: Data Flow Time in Comparison to Sources, Sinks and the Ratio of Those

Even though Arzt's evaluation also showed no correlation between the code size [3], we do for completeness also compare the runtime to the number of statements, methods and classes. Note that these refer to the Jimple intermediate representation and not Java. Figure 6.3 includes all graphs with the existing implementation on the left side and our implementation on the right side. The notation is the same as before, with the x-axis swapped out. The number of statements is uniformly distributed with some outliers. If we consider our data as two linear data sets with a structural break between the two groups, the linear regressions have a slope of close to 0. Resulting, the number of statements, methods and classes do not have an impact on the runtime.

Because the parameters mentioned above do not influence the runtime, we further investigated to find a parameter to decide the favorable direction. First, we looked at the methods containing sources and sinks. We counted the number of statements of the method, call statements and callers of the method and compared these numbers between sources and sinks. An advantage in those did not result in a faster analysis. Next, we implemented a fast intraprocedural taint analysis. It omits access paths and aliasing. Method calls are overapproximated in a similar fashion to the EasyTaintWrapper. We then counted the taints flowing into the callees and callers. Also, we did count the number of taints in the method. The drawback is that this only works when the state explosion happens inside the first method and this is not the case in the app set. Again, we could not find any resilient correlation. At this point, we run out of easily computable facts about an app that could correlate with the runtime and decided to leave the question up for future work.

Finally, we compare the number of edges in the exploded supergraph, referred to as taint propagations in section 3.2. Note that the edges in the exploded supergraph are only known after the analysis, making them useless for predictions. In Figure 6.4a we plot the edge count on the x-axis to the data flow time on the y-axis. In both graphs, we observe a linear correlation for the apps with a runtime below 500 seconds. Then there is a structural break and after that, the apps time out. A linear regression did not fit our diverse data set well with a low r^2 value, we decided to fit a function using the least-squares method. We achieved a r^2 measure of greater than 0.9 for four-degree polynomials and above. However, the good fitting curve seems overfitted to us because the apps not being close to timeouts have a good fitting linear correlation. When we look at the point where the structural break happens, we notice that backward the timeouts start after roughly $3 \cdot 10^7$ propagations. Forward, on the other hand, only gets to around $2 \cdot 10^7$ edge propagations before reaching a timeout. Such a large difference is unintuitive because the computation cost should not be much different. We split the edges up by IFDS problems in Figure 6.4b and Figure 6.4c. Interestingly, all curves have a similar steep curve except for the backward alias analysis, which curve is more shallow. This gives a possible explanation linked to

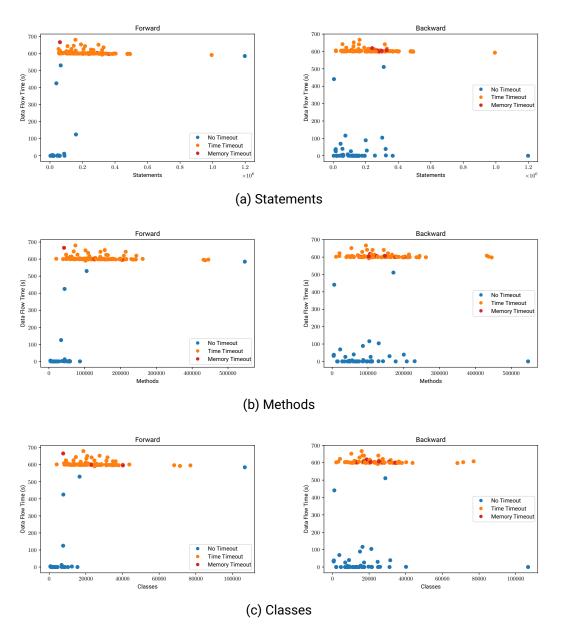

Figure 6.3.: Data Flow Time in Comparison to Code Size

the ratio of infoflow and alias edges. The alias flow functions are way simpler and, thus, should also cost less to compute. The backward analysis has a ratio biased toward the alias edges, explaining the higher edge count possible in ten minutes. Why the structural break happens could not be conclusively clarified in this work, so it is also hard to finally reason whether this also holds without such a structural break.

To conclude, our backward analysis is efficient enough to be an alternative to the existing implementation. We even found that it performed slightly better on our app set. Our evaluation shows that there is no correlation between an apriori known parameter and the runtime of FlowDroid - in both directions. Furthermore, we did not find any apriori known parameter to decide the favorable direction either. The edge propagations have shown that our implementation can analyze roughly 10^7 more edges than the existing implementation in ten minutes. Though the sample size of 200 apps is too small to generalize statements and our data was somewhat challenging to interpret with a significant standard deviation.

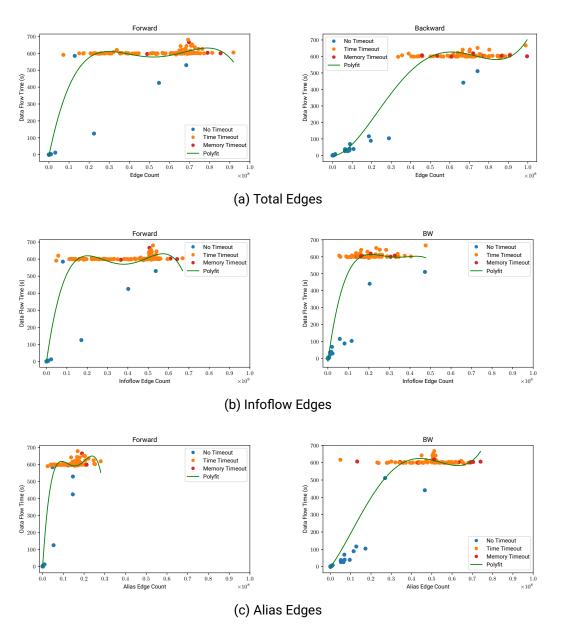

Figure 6.4.: Data Flow Time in Comparison to Edge Count

6.2.3. Memory Evaluation

Table 6.8 shows an overview of the results from the memory evaluation. Note that we only measured the memory usage of the edges in the exploded supergraph and not of the full program. Also, unlike the time measurements, the memory consumption is much more distributed across the range. The measurements with timeouts show similar values for both directions with a bias toward our implementation. Though, maximum measurements with timeouts are not meaningful because of the cut-off at ten minutes. Without timeouts, the gap gets a bit bigger. The average maximum memory consumption of our implementation is around 65 MB lower than the existing one. Especially in the 85th percentile, our implementation shines where it needs 3.3 GB less memory.

Next, we look at the memory consumption difference per app in Figure 6.5. The x-axis shows the delta maximum memory consumption in megabytes and the y-axis the frequency. Each bin is $1\,\mathrm{GB}$ wide. The delta is calculated with forward as the refrence: $m_{Backward}-m_{Forward}$. Again, we see a gathering around 0. Otherwise, the histogram has a more uniform distribution than its time counterpart. Just as in the overview, there is a slight bias towards the backward analysis. We argue this bias is related to the faster backward analysis in the app set. A faster analysis means fewer edges¹¹ and the edges should correlate linearly with the memory usage of the exploded supergraph. We looked at this by comparing the sign of the delta data flow time with the sign of the delta memory consumption. 48 apps had different signs, with 23 being negligibly close to 0. Hence, the claim is valid for 109 of 134 apps. We also calculated the Pearson correlation coefficient for the data flow time and the maximum memory consumption. For the forward analysis, the coefficient is 0.75 and 0.87 for the backward implementation. Both values indicate a correlation.

For completeness, we now validate our claim that the edges in the exploded supergraph correlate linearly with the memory consumption. We expect a linear correlation because the exploded supergraph is represented as a HashMap of edges and taints. Consider Figure 6.6 where a clear, linear correlation is visible. We confirmed our claim.

Also beneficial for the real-world usage of FLOWDROID would be to estimate the memory consumption to utilize the available resources efficiently. In Figure 6.7, we contrast the memory consumption with the number of sources, sinks and the ratio of both. Figure 6.8 shows the memory consumption in contrast to the statement, method and class count. The arrangement and legend are the same as in the time evaluation. Unlike in the time

¹¹This was at least true for apps without a timeout.

	Forward		
Metric	Avg	Median	P_{85}
Maximum Memory Consumption	$10005.68\mathrm{MB}$	$10459.48\mathrm{MB}$	15 482.98 MB
Maximum Memory Consumption Without Timeouts	1535.20 MB	6.98 MB	4952.20 MB

		Backward	
Metric	Avg	Median	P_{85}
Maximum Memory Consumption	8326.27 MB	$10008.52\mathrm{MB}$	14 539.64 MB
Maximum Memory Consumption Without Timeouts	1473.21 MB	7.33 MB	1566.61 MB

Table 6.8.: Memory Results

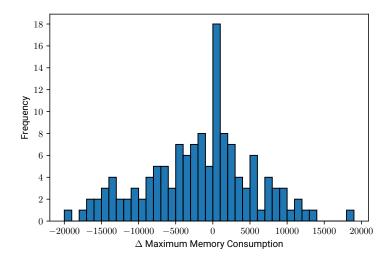

Figure 6.5.: Histogram of the Delta Maximum Memory Consumption

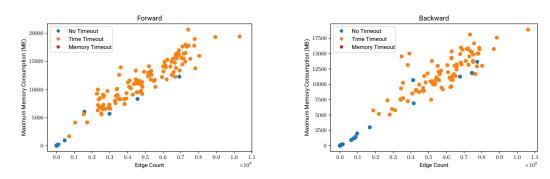

Figure 6.6.: Maximum Memory Consumption in Comparison to the Edge Count

evaluation, there is only one cluster of dots: those terminating nearly instantaneous. Otherwise, the dots seem to be randomly distributed. All graphs indicate no correlation.

To conclude, our backward analysis performed a bit better in the time evaluation, which is also reflected in the memory consumption. The results show that the observed edges are more critical for memory consumption than the code size or the sources and sinks. It is not possible to estimate the memory consumption prior nor which analysis direction will use less memory.

7. Related Work

One of the first taint analyses was based on a points-to analysis in 2005 [25]. Since then, taint analyses have made tremendous progress and gained traction in the last decade. TAJ[41] uses a context-sensitive forward thin-slice¹ for local variables and a context-insensitive points-to analysis modeling the heap. Other taint analyses utilize slicing, either as a preprocessing step [46] or using a combination of a forward and backward slice [39, 13]. Andromeda[40] was the first data flow analysis to incorporate an on-demand alias analysis. FlowDroid[6] then ported this concept to IFDS and also introduced a novel approach for modeling the Android lifecycle.

Some taint analyses also have a main backward pass similar to our approach. We take a more detailed look at them in the following paragraphs.

Lerch et al.[23] contributed FlowTwist, a static taint analysis tool based on IFDS to detect confused deputy problems² in libraries. They identify the cause of such as a combination of an integrity and confidentiality problem. For the integrity part, the sinks perform sensitive operations and the sources are attacker-controlled. In the confidentiality part, an attacker can read the sinks and sources provide sensitive data. A combination of both naturally gives a centered statement. Now, the integrity sources and confidentiality sinks are way more frequent. Thus they propose to solve the integrity part backward and the confidentiality part forward. In contrast to FlowDroid, FlowTwist focuses on a specific taint analysis case and the applicability is relatively narrow.

Allen et al.[2] present another taint analysis based on IFDS for Java used internally at Oracle. They also rely on access paths as a heap model and chose a backward-directed analysis. They justify their direction choice with the use-case of detecting web vulnerabilities where sinks are less frequent based on their intuition. Also, they have had good experiences with a backward analysis in the Parfait[43] project. Orthogonal to our work,

¹Thin-slices only include statements responsible for the explicit flow from or to a seed.

²A confused deputy is a legitimate program with more privileges tricked into misusing its authority by a malicious program.

they intentionally go without alias analysis and cut off the access paths at k=5 without appending a wildcard. Both are trade-offs to precision in favor of scalability. The taint analysis is compared to another non-public tool at Oracle on three benchmarks³ and on a not further specified Oracle product. Also, the choice of sources and sinks remain unclear and they only provide a too-brief summary of the results. Because both tools in the comparison are not public and the results are not detailed, we neither can comprehend the weak points of their analysis besides the missing alias resolving nor score the given runtimes. We are not sure whether their analysis can find non-trivial data flows because aliasing is ubiquitously in Java and access paths of k=13 are observed in real-world applications [37].

Yan et al.[44] proposed a vulnerability detection tool for PHP with a focus on web applications. They aim to detect typical web application vulnerabilities such as cross-site scripting and SQL injections using backward taint analysis. Instead of relying on nesting the problem in proven data flow frameworks, they seemingly define their custom data flow algorithm. The proposed algorithm traverses the basic blocks backward and copies the taints left after traversing a basic block to its predecessors. They do not try to reach a fixpoint; instead, they do not follow circular paths in the control-flow graph. They also emphasize their concept of "cleans": a predefined list of sanitization methods that kill the incoming taints. In FlowDroid, the same is possible using taint wrappers and both shipped implementations support such a concept. A rationale for traversing backward, which is why we included it as related work, is not provided. Generally speaking, we doubt their tool is precise enough to be useful in practice.

FLOWDROID, FlowTwist and also Allen et al.'s tool is based on IFDS. Even though IFDS seems to be a prominent choice for a taint analysis, taint analyses can also be formulated in other frameworks.

Synchronized pushdown systems (SPDS) by Späth et al.[37] are an alternative to IFDS with access paths for modeling a precise context-, flow- and field-sensitive data flow analysis. Similar to IFDS, a context-free grammar ensures the context sensitivity. Additionally, another context-free grammar model the field sensitivity. Contrary to access paths, this does not increase the domain and needs no k-limiting to be fast enough in practice. Then it computes the acceptance state of both pushdown automata to combine context- and field-sensitivity. Now, in general, an automaton with two stacks is undecidable. The separation of the problems into two reachability problems and later combining the results is decidable. However, if both automata are in an acceptance state via different paths, the algorithm overapproximates the solution. Their results look promising with a performance

³Securibench, WebGoat and OWASP.

close to access paths with k = 1. Also, they could not observe the overapproximation in practice when performing typestate analysis.

CogniCrypt[21] finds misuses of cryptographic APIs based on rules written in a domain-specific language. Internally, it also consists of a taint analysis and is based on SPDS. CodeShield⁴ is a proprietary taint analysis for cloud applications to detect vulnerabilities and also based on SPDS. SWAN⁵ is a framework for static analysis for the Swift programming language. It is based on SPDS and currently in heavy development. They plann to include a taint analysis.

Doop[10] is a framework initially for pointer analysis. In contrast to all others, it uses a declarative approach. Doop's frontend depends on Soot to create facts and encodes them in tables. The analyses are a declarative rule set written in Datalog. These rule sets are then fed into the datalog solver Soufflé[35]. P/Taint[16] extends Doop with a taint analysis. Doop is flow-insensitive and, thus, P/Taint as well.

8. Conclusion

In this thesis, we extended FlowDroid to feature a backward-directed static data flow analysis usable as an alternative to the existing forward implementation. The alternative analysis is equally precise and sound. Just like FlowDroid, our extensions are open-source and possibly will be integrated into FlowDroid in the future. To our knowledge, it is novel for a taint analysis to offer two distinct general-purpose analysis directions. Moreover, our work broadens the applicability of FlowDroid for real-world applications with a number of sources much greater than the number of sinks.

Furthermore, we evaluated our implementation against the existing one in FLowDroid. We confirmed the assumption that the runtime and also the favorable direction highly depend on the analyzed app. Both analyses put up similar numbers. In the app set we used for evaluation, we even had a statistically significant smaller runtime on our implementation. To fully utilize the benefits from a favorable direction, we investigated whether apriori known parameters can be used to predict which direction performs better. Our experiments included naturally known parameters such as code size, source and sink count and a fast preanalysis. None of which showed a correlation toward the runtime.

As the prediction of runtime remains unsolved, further research should continue on clues to choose the favorable direction beforehand. For example, it is still an open question whether specific taint analysis applications (e.g., to find SQL injections) favor one direction. Also, further work could evaluate the impact of commonly used third-party libraries on the analysis time. Additionally, our work focused on the most common context-sensitive alias analysis and other aliasing strategies were not implemented for the backward analysis. For the sake of completeness, future work could include a points-to aliasing strategy for our implementation.
